1.0 INTRODUCTION

1.1 SITE DESCRIPTION

1.1.1 Site Name and Description

Rocky Flats Environmental Technology Site (RFETS), a 6,550 acre industrial reservation is located in northern Jefferson County, Colorado. RFETS lies on two major geological units: unconsolidated surficial units (Rocky Flats Alluvium, various terrace alluvia, valley fill alluvium, and colluvium) underlain by Cretaceous bedrock (Arapahoe Formation, Laramie Formation, and Fox Hills Sandstone). Groundwater moves under confined conditions in surficial and shallow bedrock units. Additionally, confined groundwater flow occurs in deeper bedrock sandstones. Surficial soils are predominantly moderately deep to deep, well-drained clay loams of moderate to low permeability (Final Phase II RCRA Facility Investigation Remedial Investigation, Work Plan [Alluvial], U.S. Department of Energy, Rocky Flats Office, Golden, Colorado, 29 February 1991).

1.1.2 History of Operation

From the mid-1950s to the present, RFETS has been a government-owned (U.S. Department of Energy [DOE]), contractor-operated facility that fabricated nuclear weapon components from plutonium (Pu), uranium (U), and other non-radioactive metals (principally beryllium (Be) and stainless steel). Plutonium was also recovered in the facility when it reprocessed components after they were removed from obsolete weapons.

1.2 WASTE STREAM DESCRIPTION

1.2.1 Production Wastes

Radioactive and nonradioactive wastes were generated in the production processes. Plant waste handling practices involved onsite and offsite recycling of hazardous materials, onsite storage of hazardous and radioactive mixed wastes, and offsite disposal of solid radioactive materials at other DOE facilities. In the past, hazardous, radioactive, and radioactive mixed wastes were stored onsite. Primary assessments under environmental remediation programs have identified some of these storage and disposal locations as potential sources of environmental contamination.

1.2.2 Pollutants/Chemicals

The 903 Pad, located on the south eastern side of the plant, is a portion of Operable Unit No. 2 (OU2) and covers an area 113 meters wide by 120 meters long. In 1958, waste drums were stored at this location. Contaminated soil was first discovered in 1964 in an area where 210 liter drums of plutonium-laden lathe coolant oil were stored. The drums contained cutting oil and carbon tetrachloride contaminated with plutonium and uranium cuttings from nuclear weapons components machining operations.

By 1968, all of the drums had been removed, processed, and shipped offsite for disposal. The contaminated area was covered with a pad consisting of successive layers of fill dirt, gravel, and a final layer of asphalt. The level of contamination in the soil ranged between 2,000 to 300,000 disintegrations per minute (dpm)/100 square centimeters (cm²), with penetration depths of 3 to 20 cm. The plutonium metal was originally deposited as fine metallics. It oxidized into PuO₂ in the environment. The average size of the PuO₂ particles was 0.2 microns (Soil Decontamination Criteria Report, J. A. Hayden, et al, Rockwell International, November, 1990).

1.2.3 Treatability Study Background

This study was undertaken to evaluate the effectiveness of High Gradient Magnetic Separation, HGMS, in removing actinides from RF-OU2 soils. A treatability study was conducted by LESAT (Plutonium in Soils Treatability Studies, RF-OU2, T. K. Wenstrand and T. M. Murarik, Lockheed Environmental Systems and Technologies Co., Sept. 30, 1993) to evaluate the effectiveness of the TRUclean gravity separation process in removing activity from RF-OU2 soils. This report describes all aspects of the Physical Separation Treatability Test, including operating features of the TRUclean process. Because of the appropriateness of HGMS in treating small particle contamination, a residue from the TRUclean process was selected for HGMS evaluation (Sample 6 in the above referenced report). The HGMS technology is viewed as a natural complement to soil washing and gravity separation.

1.3 TREATMENT TECHNOLOGY DESCRIPTION

1.3.1 Treatment Process, Description, and Operating Features

HGMS is a form of magnetic separation in which large magnetic field gradients are used to separate micron sized paramagnetic particles. The HGMS separator consists of a high-field, superconducting solenoid magnet, where the bore of the magnet contains a fine structured matrix material. The matrix material (usually ferromagnetic) locally distorts the magnetic field and creates large field gradients in the vicinity of the matrix elements. These matrix elements become the trapping sites for both paramagnetic and ferromagnetic particles. When the field gradients are sufficiently high, weakly paramagnetic particles can be physically captured and separated from diamagnetic host materials. Because most actinide compounds are paramagnetic, magnetic separation of actinide containing mixtures is feasible. *~ 1000 G/cm* (To check)

The application of HGMS involves passing a slurry of the contaminated mixture through a magnetized volume. Ferromagnetic and paramagnetic particles are extracted from the slurry by the ferromagnetic matrix while the diamagnetic fraction passes through the magnetized volume. The magnetic fraction is flushed from the matrix later when the magnetic field is reduced to zero or the matrix is removed from the magnetized volume. The actinide containing concentrate can then be processed for disposal.

Best Available Copy

The slurry was pumped through the magnetic matrix using a peristaltic pump at constant flowrate. Feed slurry homogeneity was maintained using a mixer at the pump inlet. Back-flushing of the magnetic matrix was done at zero magnetic field and with the flow direction reversed. Feed backflush and multipass effluent samples were analyzed for contaminant concentration. Samples are analyzed for plutonium concentration using alpha spectroscopy.

1.4 Previous Treatability Studies at the Site

In addition to the LESAT Report, another soils treatability study was reported in August, 1994 entitled, "Rocky Flats Plant Soil Treatment Bench-Scale Treatability Studies (Nuclear Remediation Technologies Division, General Atomics-San Diego, California, GA-C21818) This study reported on preliminary characterization, flotation/attrition scrubbing tests, and leaching tests

2.0 CONCLUSIONS AND RECOMMENDATIONS

2.1 CONCLUSIONS

This physical separation, soil treatability study evaluated the effectiveness of using High Gradient Magnetic Separation, HGMS to treat TRUclean process residues for removal of actinides. Several separator operating parameters including superficial velocity, applied magnetic field and matrix packing density were systematically investigated along with various pretreatment protocols. The pretreatment protocols included pH adjustment, surfactant variation and organic destruction using an oxidizing agent, H_2O_2 .

The objective of any physical separation process is to concentrate the most contaminant into the smallest fraction of the feed. Therefore, results which show high separation efficiencies along with high mass fractions in the contaminant stream are undesirable. This study showed that HGMS can achieve significant separation of actinides from the processed soil residues investigated. A concentration of 51% of the activity in only 2% of the feed was achieved based on analysis of the feed and effluent.

2.2 RECOMMENDATIONS

2.2.1 Additional Studies

In view of the large number of parameters affecting the HGMS process and the complexity of the evaluation procedure, results from this initial study should be viewed as preliminary. Time was not available to repeat those particular runs in this study which demonstrated significant separation or to conduct additional tests based on conclusions reached at the end of this evaluation.

Additional studies that focus on the operating regime and pretreatment protocol of choice for this application are necessary. In conjunction with the LANL analytical model of the HGMS process, these additional data will form the basis for the scale-up to a prototype system.

HGMS is an effective physical separation process for removing small particle contamination ($<100 \mu m$). Most soil washing methods are only effective on particles greater than 50 to 100 μm . Although these traditional treatments can be effective in removing large particle contamination, their application frequently transports a significant portion of the contaminant into the fines. Once there, the contaminant is more difficult to remove and frequently requires a costly chemical treatment to reach remediation targets. As shown by this study, HGMS can be effective in treating the fines by physical separation and offers the potential to treat the bulk of the contaminated soil using physical separation methods. HGMS has been demonstrated on an industrial scale in the processing of kaolin clay and is cost effective in treating large volumes of material to remove small amounts of contaminants.

3.0 TREATABILITY STUDY APPROACH

3.1 TEST OBJECTIVES AND RATIONALE

Magnetic separation has been shown to be effective at removing small particle size contaminants ($<50\text{ }\mu\text{m}$) from similar small sized particle slurries. Because of this, magnetic separation is thought to be a compatible technology with soil washing which is appropriate for treating larger particles ($>50\text{ }\mu\text{m}$). Frequently, treatment of the larger particles using conventional technologies results in migration of the contaminant to a smaller size fraction of the waste stream. Consequently the fines are usually enriched by the contaminant. Magnetic separation is one of the few physical separation processes that is capable of treating this fine fraction. As a result, a treated waste stream residue was selected as an appropriate feed material for the magnetic separation treatability study. The thickener underflow from the LESAT processing circuit ($<150\text{ }\mu\text{m}$) was eventually selected. Activity levels of this material ranged from 100 to 144 pCi/g. The material was sieved using a 325 mesh screen to less than $53\text{ }\mu\text{m}$.

The objective of the treatability study was to evaluate the effectiveness of HGMS in removing actinide contamination from the LESAT treatment residues. Table 3 1-1 summarizes the experiment series by run.

The objectives were as follows:

Series 1 (Runs 701-705), Explore sensitivity to magnetic field. Determine the effect of concentration of sodium hexametaphosphate and the influence of superficial velocity on separation performance.

Series 2 (Runs 706-709), Determine the effect of pH and H_2O_2 pretreatment on separation performance. Also a scalping pass with a paramagnetic matrix at 2.0 Tesla was introduced. Maximum field reduced to 2.0 T.

Series 3 (Run 710-713), Combine the scalping pass with a low field ferromagnetic pass. Investigate the effect of an alternate surfactant and lower solids fraction.

3.2 Experimental Design and Procedure

Experiments were run at the LANL plutonium facility (TA-55) in PF-4, Rm 128. In Rm 128 the HGMS unit is mounted atop a vent hood.

Residue samples were wet sieved <53μm, slurred to a specified solids content (typically 10 wt%), treated with surfactant, pH adjusted with sodium hydroxide and bulk sonicated to insure particle deagglomeration. The sample was then further treated depending upon test protocol to improve particle liberation.

The test protocol required rinsing of the ferromagnetic matrix with a solution of identical pH and surfactant concentration as the test slurry. The pretreatment was followed by pass 1 of the test slurry. Upon completion of pass 1, the matrix was rinsed at field and then backflushed at zero field. The magnetics were recovered prior to pass 2. The effluent from

Pass 2, then?

pass 1 was then used as the feed for pass 2. The process was repeated for additional passes as desired.

3.3 Equipment and Materials

3.3.1 ^a Magnetic Separator

The magnetic separator consists of a solenoidal, superconducting magnet with a room temperature bore located outside the cryogenic space. The superconducting magnet is maintained at 4.2 K and can generate a magnetic field strength as high as 8 T within the warm bore. A stainless steel tube, capped at one end, extends out the top of the hood and fits into the warm bore of the magnet. The magnet is external to the hood but the high magnetic field region can be accessed from within the hood via the blind tube.

3.3.2 Test Canister-

The test canister holds either a ferromagnetic or paramagnetic matrix and provides flow deceleration zones for the slurry and backflush. Flex hoses are attached to each end of the canister permitting the canister to be removed from the magnet bore without exposing the slurry.

3.3.3 Peristaltic Pump

Fluids were pumped through the test canister with a peristaltic pump. Because the pump operates by pinching the flex tube with rotating rollers, cross contamination between the various flow streams is minimized. The pump is easily calibrated and the flow direction can be reversed.

3.4 Sampling and Analysis

The treated slurry is pumped through the magnetic separator. The emerging effluent is the decontaminated stream, whereas, the material retained by the separator is the magnetic fraction. After processing the sample, the magnetically trapped material was rinsed from the separator in a backflush operation outside the magnetic field. Feed slurry homogeneity was maintained using a mixer at the pump inlet. Feed and multipass effluent samples were analyzed for contaminant concentration. Samples were taken in test series 1 (701-705) by mixing the effluent and pouring a sample from the collection bottle. Samples were taken in test series 2 and 3 (706-709 and 710-713) by mixing the effluent in a squirt bottle and then discharging the sample from the bottom feed discharge tube. This procedure was an attempt to homogenize the effluent before sampling. All samples were collected in tared glass bottles then subsequently dried and weighed to provide data for a mass balance. Dried samples were analyzed for plutonium concentration using alpha spectroscopy by either Controls for Environmental Pollution (CEP), Santa Fe, NM (701-709) or Lockheed Analytical Services (LAS), Las Vegas, NV (710-713).

Best Available Copy

CEP and LAS both followed similar procedures for alpha spectroscopy. Received samples were quantitatively transferred to digestion beakers by acid rinsing of the sample bottles. A plutonium-242 tracer was added then the total sample was digested with nitric acid and hydrofluoric acid. LAS used microwave digestion. A boric acid or perchloric acid solution was added to the soil residue to convert the plutonium to a +4 valence state. LAS concentrated the plutonium by adding a ferric standard solution then ammonium hydroxide to the digested solid sample to precipitate ferric hydroxide with the plutonium. LAS then collected and dissolved this solid with nitric acid. The sample was then passed through an anion exchange column, washed, and the plutonium eluted. LAS proceeded with a Nd^{3+} microprecipitation of the plutonium and collection on a 0.2 mm membrane filter. CEP proceeded with electroplating of the plutonium on stainless steel discs. The filters or discs were then counted by alpha spectroscopy.

3.5 Data Management

This treatability study was conducted to evaluate the feasibility of using HGMS to address RF soil remediation. It was conducted in accordance with applicable LANL procedures and practices governing the conduct of operations of the magnetic separation equipment. Procedures have been established that govern the conduct of HGMS experiments including safe operating procedures, data handling and documentation.

Experiment flowsheets were prepared and reviewed prior to all HGMS tests. Using these flowsheets, a test specification sheet was generated assigning experiment identification numbers and defining equipment settings for the proposed test. Sample identification labels were generated for all sample containers and sample locations were identified on the experiment flowsheet. Samples were collected in labeled, tared sample bottles, for oven drying and weighing. All samples were maintained in their original, labeled sample containers.

4.0 RESULTS AND DISCUSSION

4.1 DATA ANALYSIS AND INTERPRETATION

4.1.1 Analysis of Waste Stream Characteristics

As discussed in 3 1 activity levels of the treated material ranged from 100 to 144 pCi/g. Particle sizes were less than 53 μm . More detailed information on the generation of this residue can be obtained from the LESAT Report cited in 1 2 3.

4.1.2 Treatability Study Objectives

The magnetic separation process has a number of variables which influence the results. These are listed in table 4 1 2-1 where they are categorized according to material characteristics or separator characteristics. In general, the material characteristics are determined by the application, i.e., the type of soil, the contaminant and its distribution, the particle sizes and the physical properties. Some material characteristics are controllable, such as, surfactant type and concentration, and solids concentration. However, the separator parameters are where most of the process control exists. These parameters are controlled by the matrix design, the magnetic field characteristics and the slurry fluid mechanics. It is necessary to select a set of operating parameters that are compatible with the contaminated medium and that maximize the magnetic separation process.

Table 4.1.2-1 HGMS Experiment Parameters

| Material Characteristics | Separator Parameters |
|---|--|
| Particle Size 0.5 - 50 μm | Matrix Element Size 5 - 100 μm |
| Impurity Concentration 0.4 - 2000 ppm | Matrix Element Spacing 80 - 1200 μm |
| Solids Concentration 5 - 30 wt % | Magnetic Field Strength 0.5 - 7.5 T |
| Magnetic Susceptibility* ($\times 10^6$) 129 - 1478 | Matrix Material 430 Stainless Steel |
| Surfactant Concentration 0.00 - 0.2 wt % | Residence Time 10 - 80 s |
| Slurry pH 4 - 12 | Superficial Velocity 0.25 - 4.0 cm/s |

* SI units

In conducting the treatability study for the Rocky Flats soil residue three series of tests were conducted to cover the HGMS performance envelope. These tests, defined in 3 1, were used to generate an HGMS performance map for RF residue as shown in fig. 4 1 2-1. Test series 1 addressed the full field strength range of the magnetic separator while using a ferromagnetic matrix. These results showed the largest separation efficiencies. The mass fraction retained by the matrix increases nearly linearly with increasing applied magnetic field reaching 0.3 at the 6.5 T pass. In test series 2, a paramagnetic scalping pass at 2.0 T was introduced in an attempt to reduce the magnetic fraction of the soil. In this series the second pass was done at 2 T using the ferromagnetic matrix. This series also investigated the effect of pH. Test series 3 also started with the paramagnetic scalping pass but pass 2 was executed at 0.5 T with the ferromagnetic matrix in an attempt to reduce the mass fraction retained by the matrix. This was followed by a third pass at 6.5 T.

Fig. 4.1.2-1. HGMS Performance Map for RF Soil Residue (CESAT) Showing Mass Fraction Retained and Separation Efficiency.

4.1.3 Treatability Study Results

Appendix A contains the flow diagrams and detailed data sheets for each run. There is a separate flow diagram for each test series showing the parameters for each run in the series and the location and identification of each sample taken. The mass and activity for each sample analyzed (in bold) and certain derived values (plain text) are also included and grouped by series. The mass weighted specific activity, which is the product of the mass fraction and the specific activity, is used to determine separation efficiency. The separation efficiency is calculated three ways using the mass weighted specific activity from either the feed and backflush, the backflush and effluent or the feed and effluent. If the mass and activity balance error were both zero, all three methods would give the same result. However, because of difficulties with either incomplete flushing of the matrix or inhomogeneous sampling of the effluent, one of these methods is usually more appropriate than the others.

In test series 1, the system activity balance indicated that backflushing of the matrix to remove the magnetic fraction was incomplete. The incomplete backflush was later verified by surrogate tests using the same test protocol. Therefore, separation efficiencies calculated using feed and effluent concentrations are probably more accurate than if the backflush concentrations were used. Several procedural changes were implemented in test series 2 and 3 in an attempt to improve the activity balances for these later tests. Backflushing was improved by incorporating air sparging into the liquid flush. By introducing bubbles into the flow stream, the scavenging of trapped material was improved and most of the material was liberated. In addition, effluents were sampled using bottom taps installed on the sample bottles. This modification in conjunction with the swirling motion employed to maintain particle suspension, appears to have resulted in a nonhomogeneous sampling of the effluent by preferentially collecting the heavier components containing higher activity from the mixture. Therefore, in test series 2 and 3 the feeds and backflushes had greater accuracy than the effluent samples, and efficiencies for these runs were calculated using the feed and backflush concentrations. In general, activity balances were improved in the latter experiments with errors being less than $\pm 20\%$. Table 4.1.3-1 is a results summary of the HGMS experiments. Included are the mass fractions and activity fractions for each pass of each run.

4.1.3.1 Test Series 1

The following observations were made from test series 1

- There is a high magnetic fraction in the soil residue. Even at $B=0.5$ T, the mass fraction retained by the matrix is high.
- High pH (>10) appears to aid dispersion and reduces matrix loading (see Run 701).
- Surfactant concentrations approaching 0.2 wt% may be necessary to insure high dispersion.
- Low superficial velocities (<0.5 cm/s) that normally improve separation efficiency result in unacceptably high mass retention in the matrix. (Run 704)

$u = \frac{Q}{A} = \frac{0.001 \text{ m}^3/\text{s}}{0.0001 \text{ m}^2} = 0.01 \text{ m/s} = 0.1 \text{ cm/s}$

Best Available Copy

- e Run 705 at superficial velocity of 1 0 cm/s showed an unexpectedly high separation effectiveness
- f Activity balance adversely affected by incomplete backflushing of the matrix

4.1.3.2 Test Series 2

The analysis for series 2 includes the addition of a "forward flush" which is a rinse of the matrix at field to remove solids before the backflush. Although assayed separately, it is assumed to be part of the effluent stream when calculating effectiveness. Several modifications to the test procedure were incorporated into series 2 as follows:

- a Modify sampling of the feed to assure sample uniformity
- b Backflush matrix with air sparge to improve material recovery
- c Install bottom taps on sample bottles to improve homogeneity in sampling
- d Adjust backflush solution to pH12

Results of test series 2 are as follows:

- a The scalping passes were successful in removing magnetic soil components and did not include significant activity
- b Pass 2 with the ferromagnetic matrix at 2 0 T resulted in significant mass retention along with activity removal
- c Organic destruction by peroxide pretreatment (Run 709) appears to enhance liberation of the paramagnetic actinides. Compared with Run 707, more activity was removed in the scalping pass after H₂O₂ pretreatment. However, the effect is not significant.

4.1.3.3 Test Series 3

Recognizing that the separation results from series 1 at B=0.5 T were better than series 2 results at 2 0 T, series 3 included a scalping pass at 2 0 T followed by a ferromagnetic pass at 0 5 T. Reduced solids fraction was investigated to evaluate the effect of particle interference. In addition, the H₂O₂ pretreatment was repeated along with a run to evaluate a second surfactant, sodium silicate. The procedural modifications used in series 2 were continued for series 3 (the effluent sampling problem was not discovered until after test series 3 was completed).

Best Available Copy

15

Results of test series 3 are as follows

- a The scalping pass again extracted approximately 10% of the soil without removing appreciable activity
- b Mass fractions from the second pass (B=0.5 T) were higher than observed in series 1. Therefore, the scalping pass employed in this series may not be desirable
- c Reduced solids fraction increased both separation efficiency and mass retention with no net benefit
- d The H₂O₂ pretreatment was ineffective in improving separation
- e The use of sodium silicate as a surfactant significantly increased separation efficiency (from 0.22 to 0.48) with only a slight increase in mass retention (from 0.18 to 0.26)

$$\frac{(\text{Mass Fraction} \cdot \text{Specific Activity})_{\text{mags}}}{(\text{Mass Fraction} \cdot \text{Specific Activity})_{\text{feed}}}$$

Combined efficiencies are calculated using* $E_{\text{tot}} = E_1 + E_2 - E_1 \cdot E_2$ or

Forward flushes (XXX Xf) are combined with effluent when calculating efficiencies

*Note for three passes efficiencies are calculated as follows

$$E_{\text{tot}} = E_1 + E_2 + E_3 - E_1 \cdot E_2 - E_1 \cdot E_3 - E_2 \cdot E_3 + E_1 \cdot E_2 \cdot E_3$$

MAGNETIC SEPARATION TEST

Date- 9/15/94

Location-TA55/PF4/RM128

Separator-

| Type | Magnet | Manufacturer | Descriptor |
|------|----------------------|---------------|------------|
| HGMS | 3" Superconductor | Cryomagnetics | Internal |

Objective-Test Series 3

Experimental Schematic-

- (1) Monostat D Series Varistatic pump calibrated for tubing with 4 layers of tape in tube tray and foam to center tubing in tray
- (2) Cyomagnetics 3" warm bore S/C magnetic separator
- (3) Matrix
- (4) Supply beaker
- (5) Exit and sample beaker
- (6) Nalgene tubing 1/8" ID
- (7) Nalgene tubing 1/8" ID
- (8) Magnet power supply
- (9) Stirrer

$$\frac{*(\text{Mass Fraction} * \text{Specific Activity})_{\text{mags}}}{(\text{Mass Fraction} * \text{Specific Activity})_{\text{feed}}}$$

Combined efficiencies are calculated using* $E_{\text{tot}} = E_1 + E_2 - E_1 * E_2$

Forward flushes (XXX Xf) are combined with effluent when calculating efficiencies

*Note for three passes efficiencies are calculated as follows:

$$E_{\text{tot}} = E_1 + E_2 + E_3 - E_1 * E_2 - E_1 * E_3 - E_2 * E_3 + E_1 * E_2 * E_3$$
